

PASS-THROUGH FROM EXCHANGE RATE TO PRICES IN BRAZIL: AN ANALYSIS USING TIME-VARYING PARAMETERS FOR THE 1980 – 2002 PERIOD¹

CHRISTIANE R. ALBUQUERQUE²
MARCELO S. PORTUGAL³

Abstract

The aim of the present paper is to analyze the pass-through from exchange rate to inflation in Brazil from 1980 to 2002. Initially, we developed a model of a profit-maximizing firm based on the pricing-to-market approach presented by FEENSTRA and KENDAL (1997). In order to adapt the model to the Brazilian reality, we considered the following aspects: (i) the firm sells its product both in the domestic market – where it has some pricing power – and in the foreign market – where it is a price-taker; (ii) costs are a function of the exchange rate; (iii) the degree of openness is included in the demand equation. Results show that the Kalman Filter yields better results than linear models with time-invariant parameters and that the inflationary environment and the exchange rate regime perceived by the agents affect the degree of pass-through to consumer prices. We can observe a reduction in the pass-through to consumer price indices (IPCA) or to indices with a consumer-price component (IGP-DI) after the implementation of the Real plan, and a more intense reduction after the adoption of the floating exchange rate regime in 1999. These results are in line with other estimates

presented in the literature. The pass-through to wholesale prices, however, is relatively constant all over the period.

Key words: exchange rate, pass-through, Kalman filter

JEL Classification: E31, F41

1. Introduction

In an open economy, one of the main issues that one should understand is the relation between exchange and prices. This is true especially if the economy is under an inflation-targeting regime, since the monetary authority needs to know the channel through which different variables affect the price level. By doing so, it is possible to obtain more accurate inflation forecasts concerning future inflation (reference to the Central Bank in its monetary policy decisions) and to take proper decision about the timing of monetary policy. This paper aims to analyse the pass-through of exchange rates to inflation and answer whether it is affected by current features of the economy. To do so, we will consider not only the consumer price level used by the Central Bank of Brazil as target for inflation (IPCA) but also a general prices index (IGP-DI) and a producer price index (IPA-DI).

There have been several studies about the effects of exchange rate movements on the economy, especially on prices. However, most of them are concerned with developed economies, which behave differently from the Brazilian economy. Moreover, few of these studies focus on Brazil, and many of them fail to use a longer study period that includes the years prior to the price stabilization brought about by the Real Plan. However, the absence of studies to the pre-Real plan period does not allow us to tell whether the price stabilization affects the agents' behaviour concerning the pass-through. Literature says so (see, for instance, GOLDFAJN and WERLANG, 2000), but tests about the issue are limited. Furthermore, new econometric techniques developed in recent years have made it possible to analyze the relationship between exchange rate and prices, although such alternatives remain underexplored even in industrialized countries.

Hence, the motivation of this paper comes from the importance of knowing how exchange rate shocks have affected prices under the different scenarios of the Brazilian economy. We will analyse if the macroeconomic environment affects this relation or if it is stable over time and similar to what has been observed to other countries. If not, it is necessary to look for responses to exchange rate devaluations different from those suggested by the tradition literature which considers, mainly, developed economies.

The effects of exchange rate movements on prices in different economic scenarios are of paramount importance in order for us to evaluate

whether they depend upon the macroeconomic environment, as this information is relevant for monetary policy decisions. Evidence suggests that such relation exists. An example is the different pass-through behavior of developed and emerging economies, found by CALVO and REINHART (2000), among others. The authors found a pass-through from exchange rate to inflation for emerging economies about four times higher than that of developed ones, and the variance of inflation compared to exchange rate variation was 43% for the former and 13% for the latter. The authors conclude that there is lower tolerance to exchange rate fluctuations in emerging economies.

This article is organized in seven sections, including this introduction. In the second section, the pass-through literature is reviewed. In the third section, the theoretical model used in this paper is presented, followed by the presentation of the data in the fourth section. Section five has the empirical results for the three inflation index considered, while the comparison of those results with the ones available in the literature is presented in section six. Finally, section seven concludes.

2. The *Pass-through* from exchange rate to prices

The impact of an exchange rate devaluation on prices is both direct, through an increase in import prices, and indirect, through the effects on aggregate demand. In the first case, the increase results from the share of imports in the price index as well as from the rise in input costs. On top of that, devaluation also places pressure for nominal wages to rise, due to the change in real wage. In the second case, the effects on aggregate demand are due to (i) changes in the relationship between foreign and domestic prices, (ii) the effects on interest rates, since the foreign capital movements are affected, and (iii) the wealth effect, since there may possibly be a relevant number of firms that hold foreign exchange positions. The change in the expenditure structure (between domestic and imported goods) will be greater the higher the price-elasticities of exports and imports and the degree of openness of the economy are (LOSCHIAVO and IGLESIAS, 2002).

AMITRANO, GRAUWE and TULLIO (1997) describe the following three stages in the pass-through of exchange rate devaluation to domestic inflation:

- 1) Pass-through to import prices: since there is a second-order effect on profit, which increases the average revenue and decreases the quantity demanded, the increase in profit depends on the demand elasticity. As the prices constitute a mark-up over costs, exporters might not increase them, especially if there are menu costs as well as expectations that devaluation is temporary;
- 2) Pass-through from import prices to domestic prices: the degree of pass-through depends on the characteristics of the economy: the more open an economy is (*i.e.*, stronger presence of imported goods), the higher the impact of the increase in import prices over the domestic prices is.
- 3) Price behavior after devaluation: price adjustment leads to changes in nominal wages. The degree of price adjustment depends on whether the economy is in a recession or on whether there is a restrictive fiscal policy, so as to avoid the price-wage spiral.

The studies on the exchange rate pass-through originate from the investigation of the validity of the purchasing power parity (PPP) theory. After the devaluation of the US dollar in the 1970s, US price levels did not increase as much as the exchange rate, seemingly casting some doubt on the validity of the PPP theory. Many studies were carried out⁴ to test the PPP, but the conclusion is that the parity is valid in the long run but not in the short run, that is, the pass-through from exchange rates to prices is incomplete.

Another finding is that the volatility of PPP deviations could have remained stable over time. According to ROGOFF (1996), the reasons for such deviations should not be restricted to institutional factors that are specific to the 20th century. KLEIN (1990) reminds us that the difference in the price effects between the US dollar devaluation in 1977-81 and after 1985 and its appreciation in 1982-85 offers the following empirical evidence: the pass-through is unstable and its change over time is a result of the structure of the economy. EINCHEGREEN (2002) highlights that the pass-through is not independent of the monetary regime. If the commitment

⁴ For a good literature review on pass-through and PPP tests, see GOLDBERG and KNETTER, (1996) and KLAASSEN (1999), respectively.

to inflation control is serious and if monetary policy decisions are clear, the agents will reckon the validity of a temporary exchange rate shock by the monetary authority as very unlikely, taking longer to adjust their prices in response to a change in the exchange rate. Therefore, if the pass-through is high, the short-term effect of a change in the exchange rate will be stronger on inflation than on the product, due to the reluctance to adopt a tighter monetary policy. FRANKEL (1978) found evidence of PPP in hyperinflations, which was already expected due to the predominance of monetary shocks in such situations. However, the tests rejected the parity for more stable monetary environments. All of the studies conducted reached the following conclusions: (i) real exchange rates converge to PPP in the very long term at too low a speed of convergence, and (ii) short-term deviations from PPP are high and volatile (ROGOFF, 1996).

Based on these results, the economic theory attempted to explain such deviations. The following explanations arose: the role of nontradeables in the economy (ROGOFF, 1996 and BURSTEIN, EICHENBAUM and REBELO, 2002⁵), the existence of sticky prices that may influence relative prices (DORNBUSCH, 1976), adjustment costs (DIXIT, 1989, KRUGMAN, 1988) and the existence of pricing-to-market (KRUGMAN, 1986). For applications of these theories, see KIMBROUGH (1983), FISHER (1989), GOLDBERG and KNETTER (1996), VIAENE and VRIES (1992), PARSLEY (1995), ANDERSEN (1997), FEENSTRA and KENDAL (1997), BORENZSTEIN and de GREGORIO (1999), SMITH (1999), BETTS and DEVEREUX (2000), GOLDFAJN and WERLANG (2000), LIEDERMAN and BAR-OR (2000), OBSTFELD and ROGOFF (2000), TAYLOR (2000). Among the studies about Brazil, we highlight those carried out by FIORENCIO and MOREIRA (1999), BOGDANSKI, TOMBINI and WERLANG (2000), MUINHOS (2001), CARNEIRO, MONTEIRO and WU (2002), FIGUEIREDO and FERREIRA (2002), BELAISCH (2003), MUINHOS and ALVES (2003) and MINELLA, FREITAS, GOLDFAJN and MUINHOS (2003).

5 The authors analyze inflation in 9 countries after recent exchange rate crises (after 1990) and try to explain the reason why inflation is lower than that expected by the PPP using a general equilibrium model. They point that the deviations from PPP result from low inflation in the nontradables, flight from quality and frictions in the credit market, with borrowing constrains resultant from a sudden stop in capital flows to the country after the currency crisis.

3. The theoretical model

We developed a model of a domestic firm that may choose between selling its production in the domestic or in the foreign market, or in both. The price for period t is set in $t-1$ by maximizing the expected profit. Models like this can be found in most pass-through studies that use the pricing-to-market approach. The difference here is that those models consider that the firm sells only to the foreign market and, hence, its decision is concerned with foreign prices. The model developed here considers that the firm is a perfect competitor (therefore a price taker) in the foreign market, but has some market power domestically. Hence, the firm can choose domestic prices, given its domestic and foreign demand, foreign prices, and costs involved.

Our model is based on FEENSTRA and KENDAL (1997), with some pertinent changes : (i) as previously mentioned, the decision concerns domestic prices; (ii) we consider the presence of imported inputs, implying that costs are a function of the exchange rate; (iii) we include the degree of openness in the demand function. The following equations define the model.

The total revenue of the firm in the domestic market is given by:

$$RT^{dom} = p \cdot x^{dom} (p^{dom}, p^{imp}, y, ope)$$

The total revenue resulting from exports and expressed in domestic currency is:

$$RT^{exp} = s \cdot p^{exp} \cdot x^{ext} (p^{exp}, p^*, y^*)$$

where p and p^{exp} are the prices charged by the firm in the domestic and foreign market, x^{dom} and x^{ext} are the domestic and foreign demand, p^* is the price of competitors in the foreign market, p^{imp} is the price of imports competing with the firm's product domestically, and y and y^* are the domestic and foreign income, respectively. The nominal exchange rate, expressed in domestic currency units per foreign currency, is given by s . The variable ope represents the degree of openness, included here for its relevance in explaining inflation, as pointed out by several authors. The use of this variable is justified by the studies of TERRA (1998) and ROMER (1993,1998), and by the contagion of domestic price indices by the higher

presence of import goods. In this article, the degree of openness is regarded as a proxy for the competition faced by domestic products, being therefore a relevant variable in the demand function.

According to FEENSTRA and KENDAL (1997), the firm sells z units of currency in the future market at price f_t in order to protect itself from the exchange rate risk. Thus, its profit (or loss) with the transaction is given by $z(f_t - s_t)$. Exchange rate protection is also a firm's decision variable.

Hence, the firm's profit is given by:

$$\Pi_t = (p_t - c_t) * x_t^{dom}(p_t, p_t^{imp}, y_t, op\theta) + (s_t \cdot p_t^{exp} - c_t^*) * x_t^{exp}(p_t^{exp}, p_t^*, y_t^*) + z_t * (f_t - s_t)$$

The firm maximizes the expected utility of profits. Then, the problem of the firm is given by:

$$\begin{aligned} &Max_{p_t, z_t} E_{t-1} \{ U[(p_t - c_t) * x_t^{dom}(p_t, p_t^{imp}, y_t, op\theta) + \\ &+ (s_t \cdot p_t^{exp} - c_t^*) * x_t^{exp}(p_t^{exp}, p_t^*, y_t^*) + z_t(f_t - s_t)] \} \end{aligned} \quad (1)$$

Using a second-order Taylor's expansion, we have⁶:

$$\begin{aligned} U(\Pi_t) \approx &U(E_{t-1}[\Pi_t]) + U'(E_{t-1}[\Pi_t]) * (\Pi_t - (E_{t-1}[\Pi_t])) + \\ &+ \frac{1}{2} U''(E_{t-1}[\Pi_t]) * (\Pi_t - E_{t-1}[\Pi_t])^2 \end{aligned}$$

However, it is known that $(\Pi_t - (E_{t-1}[\Pi_t])) = 0$ and that $(\Pi_t - E_{t-1}[\Pi_t])^2$ is the conditional variance of profits, herein referred to as $var_{t-1}(\Pi_t)$. Such considerations allow us to rewrite (1) as:

$$\begin{aligned} &Max_{p_t, z_t} \{ U(E_{t-1}[\Pi_t]) + \frac{1}{2} U''(E_{t-1}[\Pi_t]) * var_{t-1}(\Pi_t) \} \end{aligned} \quad (1')$$

⁶ It is necessary to disregard the rest in the equation since, otherwise, it would be necessary to incorporate the term $U'''(\cdot)$ – third derivative of the utility function – about which the economic theory has no assumptions.

To calculate $E_{t-1}[\Pi_t]$, conditional mean of Π_t , consider $E_{t-1}p_t^{\text{exp}} = p_t^{\text{exp}}$ and $E_{t-1}x_t^{\text{exp}} = x_t^{\text{exp}}$. This supposition can be made if we consider that foreign contracts for sales in t are negotiated in $t-1$. So, we have:

$$E_{t-1}[\Pi] = p_t * E_{t-1}[x_t^{\text{dom}}(p_t, p_t^{\text{imp}}, y_t, \text{ope})] - E_{t-1}(c_t) * x_t^{\text{dom}}(p_t, p_t^{\text{imp}}, y_t) + \\ + E_{t-1}(s_t) * p_t^{\text{exp}} * x_t^{\text{exp}}(p_t^{\text{exp}}, p_t^*, y_t^*) + z_t \cdot f_t - z_t \cdot s_t - c_t * x_t^{\text{exp}}(p_t^{\text{exp}}, p_t^*, y_t^*)$$

Supposing $E_{t-1}(s_t) = e_t$ and by rearranging the terms above, we obtain:

$$E_{t-1}[\Pi_t] = E_{t-1}[x_t^{\text{dom}}(p_t, p_t^{\text{imp}}, y_t, \text{ope})] * (p_t - E_{t-1}(c_t)) + \\ + x_t^{\text{exp}}(p_t^{\text{exp}}, p_t^*, y_t^*) * (e_t \cdot p_t^{\text{exp}} - E_{t-1}(c_t^*)) + z_t * (f_t - e_t) \quad (2)$$

Calculating the conditional variance of profits and naming $E_{t-1}[(s_t - e_t)^2]$, which is the conditional variance of the exchange rate, as \mathbf{s}_s^2 , we have:

$$\text{var}_{t-1}(\Pi_t) = E_{t-1}\{[\Pi_t - E_{t-1}(\Pi_t)]^2\} \\ \text{var}_{t-1}(\Pi_t) = \mathbf{s}_s^2 * [x_t^{\text{exp}}(p_t^{\text{exp}}, p_t^*, y_t^*) - z_t]^2 \quad (3)$$

Using (2) and (3), (1') can be rewritten as:

$$\text{Max}_{p_t, z_t} \{U[E_{t-1}[x_t^{\text{dom}}(p_t, p_t^{\text{imp}}, y_t, \text{ope})] * (p_t - E_{t-1}(c_t)) + \\ + x_t^{\text{exp}}(p_t^{\text{exp}}, p_t^*, y_t^*) * (e_t \cdot p_t^{\text{exp}} - E_{t-1}(c_t^*)) + z * (f_t - e_t)] \\ + \frac{1}{2} U''[E_{t-1}(\Pi_t)] * \mathbf{s}_s^2 * [x_t^{\text{exp}}(p_t^{\text{exp}}, p_t^*, y_t^*) - z_t]^2\} \quad (1'')$$

Deriving the equation above in relation to z_t , a first-order condition is that:

$$U'(E_{t-1}(\Pi_t)) * (f_t - e_t) - \\ - U''(E_{t-1}(\Pi_t)) * \mathbf{s}_s^2 * x_t^{\text{exp}}(p_t^{\text{exp}}, p_t^*, y_t^*) * p_t^{\text{exp}} - z_t^* = 0$$

From where it follows that:

$$z_t^* = [-U'(E_{t-1}(\Pi_t)) * (f_t - e_t) / U''(E_{t-1}(\Pi_t)) * \mathbf{s}_s^2] + \\ + x_t^{\text{exp}}(p_t^{\text{exp}}, p_t^*, y_t^*) * p_t^{\text{exp}}$$

However, $-U'(E_{t-1}(\Pi_t)) / U''(E_{t-1}(\Pi_t))$ is the inverse of the Arrow-Pratt absolute risk aversion coefficient (R_u). Hence,

$$z_t^* = ((f_t - e_t) / R_u * \mathbf{s}_s^2) + x_t^{\text{exp}}(p_t^{\text{exp}}, p_t^*, y_t^*) * p_t^{\text{exp}} \quad (4)$$

The optimal future contract has a term that represents the speculative purchase (or sale) of foreign currency, and a second term that corresponds to the contribution of foreign sales to the total revenue of the firm⁷.

Using (2), (3) and (4), equation (1) can be rewritten as:

$$\text{Max}_{p_t, z_t} [U[E_{t-1}(x_t^{\text{dom}}(p_t, p_t^{\text{imp}}, y_t, \text{ope})) * (p_t - E_{t-1}(c_t)) + x_t^{\text{exp}}(p_t^{\text{exp}}, p_t^*, y_t^*) * (e_t p_t^{\text{exp}} - E_{t-1}(c_t^*))] + \\ + [(f_t - e_t) / R_u * \mathbf{s}_s^2] + x_t^{\text{exp}}(p_t^{\text{exp}}, p_t^*, y_t^*) * p_t^{\text{exp}}] * (f_t - e_t)] + \\ + \frac{1}{2} U''[E_{t-1}(\Pi_t)] * \mathbf{s}_s^2 * (x_t^{\text{exp}}(p_t^{\text{exp}}, p_t^*, y_t^*) - (f_t - e_t) / R_u * \mathbf{s}_s^2) + x_t^{\text{exp}}(p_t^{\text{exp}}, p_t^*, y_t^*) * p_t^{\text{exp}}]^2 \quad (1''')$$

The first-order condition with respect to p_t is:

$$U' E_{t-1}(\mathbf{P}_t) * \{[\delta E_{t-1}(x_t^{\text{dom}}(p_t, p_t^{\text{imp}}, y_t, \text{ope})) / \delta p_t] * (p_t - E_{t-1}(c_t)) + E_{t-1}(x_t^{\text{dom}}(p_t, p_t^{\text{imp}}, y_t) - \\ - R_u^{-2} * [(f_t - e_t)^2 / \sigma_s^2] * \frac{\delta R_u}{\delta p_t}\} - \frac{1}{2} U''(E_{t-1}(\mathbf{P}_t)) \sigma_s^2 * \{-2 * R_u^{-3} * [(f_t - e_t)^2 / \sigma_s^2] * \frac{\delta R_u}{\delta p_t}\} = 0$$

From where we get p_t , the optimal price to be charged by the firm:

$$p_t = E_{t-1}(c_t) - E_{t-1} [x_t^{\text{dom}}(p_t, p_t^{\text{imp}}, y_t, \text{ope})] / ? \quad (5)$$

where h_t is the price-elasticity of demand

$$(\mathbf{d}E_{t-1}(x_t^{\text{dom}}(p_t, p_t^{\text{imp}}, y_t, \text{ope})) / \mathbf{d}p_t).$$

⁷ This result is similar to the one presented by FEENSTRA and KENDAL (1997). The difference lies in the second term, which, in that work, is the total revenue the firm should obtain with external sales expressed in domestic currency.

The next step is to transform the equation above into an equation that can be tested empirically. To do that, we need to make a few assumptions concerning the demand and cost functions. Let us consider the demand function presented in FEENSTRA and KENDAL (1997):

$$x_t^{dom}(p_t, p_t^{imp}, y_t) = (\mathbf{a} / p_t) - (\mathbf{b} / p_t^{imp}) * y$$

This function has the requested properties, that is, it is decreasing in the domestic price and increasing in the price of the imported competitor and in the income. Besides, as pointed out by the authors, such a function allows the demand for the domestic product to be null. This will happen for domestic and imported price levels that are sufficiently high for the whole market to be supplied. In such case, the local product will be demanded if $p_t < q_t(\mathbf{a}/\mathbf{b})$. As previously mentioned, a difference in relation to the original study is that here we will consider that variable y will not be regarded as income but as the deviation from the potential product instead⁸.

Let us also consider that the domestic price of the imported good in an imperfect market depends not only on the actual import price but also on the presence of other foreign competitors in the same market. Thus, the higher the degree of openness, the less freedom the importer will have to pass elevated mark-ups on to the consumer. Therefore, we consider that some weight is placed on competition when setting the prices for the consumer. Besides, prices of the imported goods are also function of income. So p^{imp} is given by:

$$p^{imp} = (p^M)^f . ope^{-J} y^g, \quad \mathbf{f} > 0, \mathbf{J} > 0, \mathbf{g} > 0$$

where p^M is the price imports have when they arrive in Brazil and ope is the degree of openness of the economy.

The degree of openness in the demand function also presents the required properties. Deriving the demand function in relation to the variable ope , we observe a negative sign: the higher the degree of openness (and hence, market competition), the smaller the demand for a certain product.

8 The product deviation from its natural level, as a proxy for idle capacity, is a relevant variable in pass-through and inflation studies. The idea is that during a recession (i.e., with high idle capacity), there is more difficulty in passing cost increases on to final prices

Likewise, using the function above to derive p in relation to ope , the sign is also negative⁹. This sign is expected because, according to the literature, there is an inverse relationship between inflation and the degree of openness, whose reasons may be found, for instance, in TERRA (1998) and ROMER (1993, 1998). According to TERRA (1998), there is a negative relationship between inflation and the degree of openness in economies with high level of external indebtedness, since, if the major part of the debt belongs to the public sector, taxes will have to be increased. The less open an economy is, the higher the exchange rate devaluation required to produce trade surpluses, leading to an increase in the liabilities expressed in domestic currency and, hence, a greater need to obtain revenues through the inflationary tax. ROMER (1993, 1998) also establishes a negative relationship, but the cause lies in the implicit commitment of the monetary policy: the more closed an economy is, the greater the benefits of surprise inflation will be¹⁰.

Substituting the demand function above in equation (5) we have:

$$P_t^2 = E_{t-1}(c_t) \cdot \left[\left(\frac{\alpha}{\beta} \right) (y_{t-1}^{-1}) P_{t-1}^{M-\phi} ope_{t-1}^{\phi} \right] \quad (6)$$

Next, some assumptions should be made about the costs. Since there are imported inputs, let us consider that the costs are an increasing function of the exchange rate, assuming the form $c_t = As^q$. Let us also consider that the purchase of inputs to produce goods in t is made in $t-1$, therefore applying the exchange rate in effect at the time. Hence, $c_t = As_{t-1}^q$ ¹¹.

⁹ $\delta x(\cdot)/\delta ope = -\theta\beta y(p^M)^{\phi} ope^{\phi-1} < 0$ e $\delta p(\cdot)/\delta ope = -\alpha\theta\beta y(p^M)^{\phi} ope^{\phi-1} / (x+by(p^M)^{\phi} ope^{\phi})^2 < 0$.

¹⁰ However, one must be aware of the difference between the negative relationship between the degree of openness and inflation and the positive relationship between the degree of openness and the exchange rate pass-through, as recalled by GOLDFAJN and WERLANG(2000). The latter relationship is positive because a more open economy means a higher presence of imported goods in the price index. The higher the contribution of imported goods, the higher the increase in the price index whenever an exchange rate devaluation occurs.

¹¹ Other assumptions may be made in order to remove the expectation operator from the equation. One of them consists in adopting the assumption of FEENSTRA and KENDAL (1997). If costs follow a time process such as $\text{Inc}_t = \text{Inc}_{t-1} + \epsilon_t$, where $\epsilon_t = \epsilon_{t-1} + v_t$ (v_t is a white noise), then $E_{t-1}(\text{Inc}_t)$ is equal to Inc_{t-1} plus a residual term. However, the authors do not consider costs as a function of exchange rates, but we can reach the same conclusion if we assume such relationship and if we also consider that the exchange rate follows a random walk as the one described here. Considering that costs are negotiated in $(t-1)$ to be paid in t with the exchange rate in effect at that period would add some algebraic complexity to the solution, since we would have to consider the term $E_{t-1}(s_t)$ throughout the exercise. For simplification, we chose the first alternative presented here.

Thus, the price equation is expressed as

$P_t^2 = A s_{t-1}^{\theta} (\alpha/\beta) y_{t-1}^{-1} P_{t-1}^{M-\phi} ope_{t-1}^{-\phi}$. Applying the natural logarithm on both sides of the equation we have:

$$\ln p_t = (1/2) \ln(A\alpha/\beta) + (1/2)\theta \ln(s_{t-1}) - (1/2)\phi \ln(p_{t-1}^M) - (1/2) \ln y + \vartheta \ln(ope) \quad (6')$$

generalizing

$$\ln p_t = \mathbf{m} + \mathbf{a}_1 \ln s_{t-1} + \mathbf{a}_2 \ln y_{t-1} + \mathbf{a}_3 \ln ope_{t-1} + \mathbf{a}_4 \ln p_{t-1}^M + \mathbf{e}_t \quad (6'')$$

where $\mu = (1/2)\ln(A\alpha/\beta)$, $\alpha_1=(1/2)\theta$, $\alpha_2=-1/2$, $\alpha_3=(1/2)\vartheta$, $\alpha_4=-(1/2)\phi$ and ϵ_t is a white noise error.

First, a linear model with constant parameters will be used to test equation 6'', in order to check whether the parameters changed along the study period, especially parameter α_1 . If there is any evidence of time instability, a specification with time-varying parameters will be tested through the Kalman Filter, an algorithm used to compute the optimal value of a state vector.

Before we proceed, an additional comment is required: models like the one developed here (and adopted in many works concerning the pricing-to-market) do not present, in their development, the inertial component in inflation. However, since this is a non-questionable factor in the Brazilian recent economic history, the results of the empirical tests with the Kalman Filter have that element, by using the time-varying intercept. Therefore, the absence of inflationary inertia in the theoretical model do not imply in its absence in the empirical analysis.

4. Data

We used a quarterly sample, from 1980 to 2002, and data were obtained from the websites of their respective sources¹². To deseasonalize the series, we used the X-11 method. The following variables were used:

¹² <http://www.fgvdados.com.br>, <http://www.bcb.gov.br> and <http://www.ibge.gov.br>.

- a) *igp_des*: Deseasonalized generalized price index -internal availability (IGP-DI /FGV);
- b) *ipa_des*: Deseasonalized wholesale price index – internal availability (IPA-DI/FGV);
- c) *ipca_des*: Deseasonalized broad consumer price index (IPCA/IBGE);
- d) *cambio*: Nominal exchange rate, selling values, in Brazilian reais vis-à-vis US dollars, monthly average;
- e) *gap*: Deviation of GDP from its potential level. The first step for its calculation consisted in deseasonalizing the GDP series provided by IBGE. After that, the trend of the series was extracted using the Hodrick-Prescott filter. The difference between the actual series and that trend is the proxy for the GDP deviation from its potential level. The expected sign of this variable in the price level is positive: if GDP is below its level, a decrease in the product implies a decrease in its gap value, which becomes more negative. Thus, we expect an increase in recession to reduce prices. If the economy is strong, with GDP above its potential level, an increase in the GDP – which causes a rise in prices – increases the positive gap value;
- f) *ope*: Represents the degree of openness of the economy. It is calculated as the ratio between the sum of exports and imports and the GDP. As previously mentioned, the response of prices to this variable has a negative sign;
- g) *p_imp_des*: Refers to the deseasonalized import price index. A rise in import prices is expected to increase prices directly, due to the presence of imported goods in the price index, and indirectly, due to its presence in production costs.

5. Empirical analysis

5.1. Stationarity and cointegration

The first step before working with the series is to check whether they are stationary. In this regard, Tables 1 and 2 show the results of stationarity tests in level and in first difference, respectively. The optimal number of lags for AD&F tests was based on Akaike information criteria.

Note that the *variable gap* is stationary, while the variables *openess*, *ipca_des*, *ipa_des* and *preço_imp_des* have unit roots, both on the *Augmented Dickey Fuller* test (AD&F) and on the *Phillip-Perron* test (PP). For the variable *cambio*, the ADF test described the series as stationary, whereas the PP test indicated the presence of unit roots¹³. For the IGP-DI, the ADF test shows the series as nonstationary, at a 5% significance level, both in level and in first difference. The PP test presented the series as being I(1). In Table 2, the variables *ope*, *e*, *p*, *pm*, *igp*, *ipa* express the variables *openess*, *cambio*, *ipca_des*, *preço_imp_des*, *igp_des* and *ipa_des*, respectively, in first difference.

TABLE 1 –Stationarity test for variables in levels

Variable	ADF test statistics	Phillip-Perron test statistics
cambio	-2.0976(3) ^{*b}	-1.0816 ^a

13 The Dickey-Fuller GLS and Kwiatkowski-Phillips-Schmidt-Shin tests also identified *cambio* as I(1).

With regard to cointegration tests, Tables 3 to 5 show that cointegration vectors are not present in any of the three cases considered (IPCA, IGP-DI, IPA). Therefore, we have to use the first difference of the variables.

TABLE 3 – Cointegration test - IPCA

5.2. Linear models

First we tested the model using OLS. For all price indices, as shown in Appendix I, the models showed specification errors (Reset test), parameter and/or variance instability (CUSUM of squares tests), autocorrelation of residuals (for IGP and IPA) and Arch residuals (for IPA). Given these results and the previous knowledge about changes in the inflation pattern and exchange rate policy after 1994, we made two attempts to model these changes: to split the sample into two periods and to include dummy variables in the exchange rate coefficient.

The two subsamples refer to the pre- and post-Real periods, and are used to check whether there are significant changes in the parameters in these periods. The first subsample, covering the pre-Real plan, goes up to 1993, while the second one starts in 1995. The year 1994 was not included in any of the samples because we consider it as a transition period, where agents could predict the changes in the monetary policy. Inflation indices were still influenced by the high inflationary levels of the previous period. Hence, the pattern observed in 1994 may be neither characteristic of the pre-Real period nor of the post-Real one.

The inclusion of dummy variables to indicate the three major periods of Brazilian monetary policy concerning inflation and exchange rate aims at verifying whether such inclusion is enough to model the breaks suggested in the previous analysis. The model will therefore have the following form:

$$P = \mu + (\alpha_1 + \alpha_4 d4 + \alpha_5 d5) * e_{t-1} + \alpha_2 * gap_{t-1} + \alpha_3 * ope_{t-1} + \alpha_4 * PM_{t-1} + \varepsilon_t \quad (7)$$

Dummy variables $d4$ and $d5$ represent the post-Real period with pegged and floating exchange rates, respectively, with unity values assigned to the periods t they intend to represent. Thus, the exchange rate coefficient for the pre-Real period is α_1 , while for the 1994:III to 1998:IV period it is $\alpha_1 + \alpha_4$, and $\alpha_1 + \alpha_5$ between 1999:I and 2002:IV.

Splitting the period into two subsamples is not enough to eliminate specification errors, parameter instability, and presence of autocorrelation (see Appendix I). The inclusion of dummy variables allowed correcting such problems and perceiving the change in the exchange rate coefficient after the Real Plan. However, we cannot reject the null hypothesis that α_1

+ α_{j5} equals zero, which means that the pass-through from exchange rate to inflation after 1999 is null – a contradiction from the economic standpoint.

Parameter instability, significant differences between the variables for the post-Real sample, specification errors in the model pointed out by Reset tests may be an indicative sign that analyzing the period using models with time-invariant parameters is not the most adequate approach, especially when we consider the exchange rate pass-through, whose behavior changed after 1995.

We also consider that the specification errors in the model could be resultant from the absence of the inertial term. However, the inclusion of AR terms did not correct the specification problems previously mentioned.

The inclusion of dummy variables in the exchange rate coefficient – as in equation 7 – avoids some of the problems detected by the tests, especially residual autocorrelation and parameter and/or variance instability. However, if on the one hand the tests revealed some instability in the exchange rate coefficient, on the other hand, they yielded results that do not seem coherent since the pass-through from exchange rate to inflation is statistically null for the three indices. The correction of the instability and autocorrelation by means of dummy variables shows that the exchange rate coefficient should not be regarded as time-invariant. The incapability of such dummy variables to identify the changes that occurred after the floating exchange rate regime led us to test the initial model using the Kalman Filter.

5.3. The Kalman Filter analysis

The Kalman Filter was applied in a general-to-specific process. First, we tested a model where all coefficients were stochastic. Afterwards, we restricted the number of stochastic coefficients based upon the statistical significance of the variance coefficient in the state equation and upon the information criteria. Thus, the variables whose state variance coefficients (parameters $\vartheta_{\mu,t}$ and ϑ_{oit} in equations 8) were not significant were considered as having time-invariant parameters. The advantage of such procedure is that if we consider that only the exchange rate coefficient is stochastic and that other coefficients vary over time, the results found for the exchange rate will incorporate the movements in those coefficients regarded as time-invariant.

Another decision refers to the space equation format, i.e., whether it is a random walk or an AR(1) process. In the first case, the effects of the stochastic coefficients are assumed to be permanent, whereas in the second case, the effects, although persistent, are regarded as temporary. Since exchange rate shocks are not permanent – once they are passed on to prices, in different degrees, – we adopted the AR(1) format for the space equation. If the estimated AR parameter is close to unity, a random walk formulation will be tested.

We tested the inclusion of dummy variables in the state equation of the exchange rate parameter in order to verify whether the exchange rate regime or the price dynamics affects that equation. Thus, three dummy variables were tested. The first of them – d_1 – assumed a value equal to zero for periods when there was a managed exchange rate system in Brazil, and equal to one for the other periods with officially floating exchange rates (March 1990 to February 1995 and January 1999 to December 2002). The second dummy variable – d_2 – differs from d_1 as it assumes a value equal to the unit in those periods with effectively and not only officially floating exchange rates. Therefore, d_2 refers to the period known as managed exchange rate system. “Managed” means that the monetary authorities interfere in the exchange rate market, but have no intention to maintain the exchange rate stable at a given level regarded as ideal by the government, as occurred between March 1990 and July 1994 (see ARAUJO and FILHO (2002)). Thus, d_2 assumes a unit value from July to September 1994 and from January 1999 on, and a zero value for the other periods. The purpose of such distinction is to verify whether the announced exchange rate regime is relevant to price setting or how exchange rates behave in practice. Finally, the third dummy variable – d_3 – aims at comparing the price dynamics in high-inflation periods with stable periods. Therefore, d_3 has a unit value for the pre-Real period, and a zero value for the post-Real period.

Chart 1 – Tested Dummies

<i>Dummy</i>	Plan	Period with a unit value
D ₁	Officially floating exchange rates	1990:I – 1995:I; 1999:I – 2002:IV
D ₂	Managed exchange rate system	1994:III ; 1999:I – 2002:IV
D ₃	High inflation	1980:I – 1994:II
D ₄	Real Plan with pegged exchange rates	1994:III – 1998:IV
D ₅	Real Plan with floating exchange rates	1999:I – 2002:IV
D _{cruz}	Cruzado plan	1986:I – 1986:III
D _{bress}	Bresser plan	1988:III
D _{ver}	Summer plan	1989:I
D _{col1}	Collor 1 plan	1990:I – 1990: II
D _{col2}	Collor 2 plan	1991:I – 1991:II
D _{real}	Real plan	1994:III – 2002:IV

We also tested dummy variables related to the economic plans announced in the course of the study period, according to CATI, GARCIA and PERRON (1999). The variables have a unit value throughout the period in which economic plans were in effect, and a zero value for the other periods, except for the post-Real period, which was not included in the referred paper. Two dummies were assigned to the post-Real period: d_4 , with a unit value between July 1994 and December 1998, and d_5 with a unit value after the exchange rate devaluation in 1999. The dummy variables are shown in Chart 1.

The initial model had therefore the following form¹⁴:

$$\begin{aligned}
 p &= \mathbf{m}_t + \mathbf{a}_{1,t} e_{t-1} + \mathbf{a}_{2,t} gap_{t-1} + \mathbf{a}_{3,t} ope_{t-1} + \mathbf{a}_{4,t} pm_{t-1} + \mathbf{e}_t \\
 \mathbf{m}_t &= c_1 + c_2 \mathbf{m}_{t-1} + \mathbf{J}_{\mathbf{m},t} \\
 \mathbf{a}_{1,t} &= a_{11} + a_{12} \mathbf{a}_{1,t-1} + \sum_{i,j} a_{1,j} d_i + \mathbf{J}_{\mathbf{a}1,t} \\
 \mathbf{a}_{2,t} &= a_{21} + a_{22} \mathbf{a}_{2,t-1} + \mathbf{J}_{\mathbf{a}2,t} \\
 \mathbf{a}_{3,t} &= a_{31} + a_{32} \mathbf{a}_{3,t-1} + \mathbf{J}_{\mathbf{a}3,t} \\
 \mathbf{a}_{4,t} &= a_{41} + a_{42} \mathbf{a}_{4,t-1} + \mathbf{J}_{\mathbf{a}4,t}
 \end{aligned} \tag{8}$$

The final model, however, changed according to the inflation index used, as shown in the following sections.

14 In order to ensure a positive variance term, e_t and $\vartheta\alpha_{1,t}$ were defined as $\text{var}[\exp(e_t)]$ and $\text{var}[\exp(\vartheta\alpha_{1,t})]$, respectively. The choice for naming the variables through the text just as e_t and $\vartheta\alpha_{1,t}$ was adopted for simplification .

5.3.1 IPCA

For IPCA, the model to be estimated was¹⁵:

$$p = \mathbf{m}_t + \mathbf{a}_{1,t}e_{t-1} + \mathbf{a}_2gap_{t-1} + \mathbf{a}_3ope_{t-1} + \mathbf{a}_4pm_{t-1} + \mathbf{e}_t$$

$$\mathbf{m}_t = c_1 + c_2\mathbf{m}_{t-1} + \mathbf{J}_{m,t}$$

$$\mathbf{a}_{1,t} = a_{11} + a_{12}\mathbf{a}_{1,t-1} + a_{13}d_2 + \mathbf{J}_{a1,t}$$

In Table 6 - which shows the results obtained – we note that the coefficient of *gap* ($\alpha_{2,t}$) is significant and has the expected sign. The coefficient of the degree of openness ($\alpha_{3,t}$), although it contains the expected sign, is not significant. The coefficient $\alpha_{4,t}$, which refers to import prices, does not contain the expected positive sign, and is not significant.

As far as variances are concerned, we note that the variances of the state equation for the intercept and the exchange rates ($\vartheta_{\mu,t}$, $\vartheta_{\alpha_{1,t}}$) have significant coefficients, which means that they are effective. In other words, the coefficients are actually varying over time and, hence, the Kalman Filter captures changes in these coefficients that a model with constant parameters would not.

15 Appendix I shows some other models tested for IPCA, IGP-DI and IPA using the Kalman Filter.

As for the intercept, we observe that c_1 is not significant whereas c_2 is. This means that, although the mean of the intercept is null, shocks are persistent on it. Such a result is expected in an inflation model if we consider that this variable captures the inflationary inertia of the period, since the Kalman filter with varying parameters on the constant is equivalent to estimating the stochastic trend of the series. Therefore, we can consider that the intercept, to some extent, represents the inflationary inertia. Graph 1 shows that this coefficient becomes not only smaller but also more stable after the implementation of the Real Plan, underscoring the idea of a remarkably low inflationary inertia after price stabilization.

Concerning the behavior of the exchange rate coefficient, $\alpha_{1,t}$, a_{11} is significant, while a_{12} is not. In the former case, the exchange rate pass-through is important in explaining prices, regardless of the period. However, shocks on this coefficient do not propagate through time. In other words, the stochastic process resembles a white noise. The forecast for period $t+1$ is given by $E(\mathbf{a}_{1,t+1}) = a_{11} + a_{12}\mathbf{a}_{1,t-1} + a_{13}d_2$. Since a_{12} and a_{13} are indifferent from zero, the best forecast of the value for the exchange rate *pass-through* ($\alpha_{1,t+1}$) is the mean of the process, a_{11} . Hence, an increase of 1% in the exchange rate causes an average increase, in the period analyzed, of 0.49% in the inflation rate. Finally, the dummy variable d_2 , is significant, implying that the intervention in the exchange rate market affects the pass-through dynamics.

By analyzing Graph 2, which shows the smoothed estimates of the pass-through coefficient, we can clearly identify three different periods in the behavior of $\alpha_{1,t}$. These periods may be associated with three different moments of the Brazilian economy throughout the sample period.

The first period goes from 1980 until the implementation of the Real plan. A considerably high and volatile exchange rate pass-through characterizes this period, with peaks close to one, which illustrates the exchange rate/price spiral typical of high inflations. At a first glance, we could attribute this to some circularity between inflation and prices, since in that period the exchange rate regime followed a “Purchase Power Parity Rule” (the nominal exchange rate was determined according to the difference between domestic and foreign inflation). However, problems resultant from a Granger-Causality in both directions between inflation and exchange rates (as pointed out in GUTIERREZ, 2002) do not affect the

results presented here because we do not work with contemporaneous variables. What is being reflected here is the spiral “exchange rate/prices”: the exchange rate in $t-1$ affects inflation in t (that affects exchange rate in $t+1$ by the PPP rule which, in its turn, affects inflation in $t+2$), but inflation in t do not affect exchange rate in the previous period. Coefficients close to 1 confirm the result in FRANKEL (1978) of evidence of the PPP in hyperinflations and the spiral above mentioned: in moments of “unannounced economic packages”, when the freezing of exchange rates and/or prices was adopted, the coefficient shows sudden drops returning, afterwards, to its previous levels. The mean pass-through for the period is 0.49 (see Appendix II), but there are moments of sharp reductions that may be associated with the different economic plans (1986:II, 1987:III, 1988:IV, 1990:II, 1991:II, 1992:I).

The second period covers 1995 to 1998, where the mean drops to 0.42 (Appendix II), and so does its volatility, showing a more stable behavior over time. Finally, the third period starts in 1999, when the floating exchange rates were adopted and the coefficient remarkably decreased, yielding a mean value of around 0.04.

At first, the strong decrease in 1999 is not expected since, in large devaluations, a higher pass-through from exchange rates to prices is assumed. However, the Brazilian economic scenario at the time, with recession and extremely volatile exchange rates, may have favored a contrary behavior. In this scenario, price setters would not be able to increase their prices proportionately to the devaluation as they used to do before, due to the economic slowdown, which inhibits demand, and to the uncertainty about the future. If the exchange rates do not maintain that higher level, the costs to reverse the price increase (menu costs and reputation costs, for instance) could be much higher¹³. Furthermore, in times of pegged exchange rates, changes in exchange rates are considered to be permanent and, therefore, agents have an extra incentive to adjust their prices as soon as possible. However, in times of floating exchange rates, the resulting uncertainty and the presence of factors such as menu costs and hysteresis (see DIXIT, 1986), make agents “wait and see” until they can be sure that the (de)valuation is permanent and until they know the new exchange rate level.

13 For a detailed discussion, see DIXIT (1986).

Graph 1 – IPCA: Smoothed Estimate of m_t

Graph 2 – IPCA: Smoothed Estimate of $a_{1,t}$

5.3.2 IGP-DI

The IGP-DI model is quite similar to that used for IPCA, with time-varying coefficients for the exchange rate and intercept. Although d_2 was not significant, its inclusion yielded better results than the inclusions of other dummy variables (also not significant) or than its absence. The three periods related to the behavior of the exchange rate coefficient are more noticeable than in the case of IPCA, and the decrease in 1999 is less intense as well, (Table 7 and graphs 3 and 4).

As for the significance of fixed parameters and their signs, import prices are still indifferent from zero, and so is the degree of openness, both with the expected sign. a_2 , on its turn, is significant and has the expected sign.

With regard to the exchange rate coefficient, again, it has a white noise with drift. We may also note that most of the sharp reductions in the coefficients are the same ones found for IPCA (1986:II, 1987:III, 1989:I, 1989:IV, 1990:II to 1990:4, 1991:I, 1991:II, 1992:I, 1994:I). The coefficient – or the exchange-rate elasticity of prices - is 0.33 for the whole period. Calculating the mean of the filtered estimates of $a_{1,t}$ for the three periods, we have an elasticity of 0.33 for 1980:I to 1994:II – if we remove the above mentioned periods from the sample, this value goes to 0.40 – 0.27 from 1994:III to 1998:IV and 0.07 from 1999:I on (see Appendix II). Thus, the Real plan led to a decrease in the pass-through, but the change in the exchange rate system and the adoption of the inflation-targeting regime in 1999 caused a sharper decrease in this coefficient.

The model was also tested without the dummy d_2 , once this was not statistically significant. The results are different from the ones presented here only after 1999:1, once the change in the pass-through coefficient is not identified. In this case, the pass-through from the exchange rate to the IGP-DI remains at around 0.27. However, a_{11} and a_{12} are not statically different from zero under such formulation, that is, the pass-through follows a random walk. Since a result of a zero pass-through from exchange rate to prices is counter-intuitive, we opted to keep the model with the dummy.

Table 7 Kalman Filter : IGP-DI Results

Graph 3 – IGP-DI: Smoothed Estimate of m_t **Graph 4 – IGP-DI: Smoothed Estimate of $\alpha_{1,t}$** 

Graph 5 draws some attention to the comparison of both indexes through the filtered estimates of the exchange rate coefficients in both cases (IPCA and IGP-DI) after the Real plan. Until 1999, the exchange rate pass-through to IPCA was, on average, higher than to the IGP-DI, which justifies the selection of the latter one as the index used to realign contracts. After 1999, we have an opposite situation, when the IGP-DI – which consists mostly of wholesale prices - had a higher pass-through, on average, than IPCA has.

**Graph 5 – Filtered Estimates of $a_{1,t}$ for the Post-Real period:
IGP-DI vs. IPCA**

5.3.3 IPA

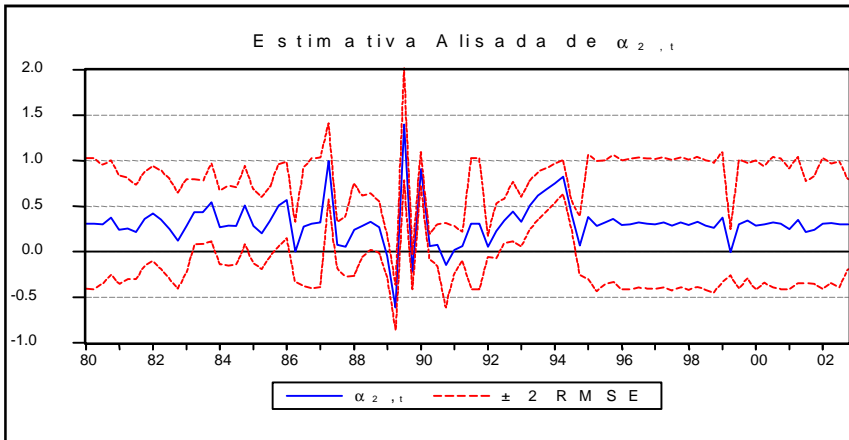

Concerning the use of the Kalman Filter to the IPA, the dynamics differ from the previous ones only by the absence of dummies in the state equation.

We notice the presence of the inertia also in the IPA-DI, as shown by the time-varying intercept in graph 6. Again, $a_{1,t}$ follows a white noise with drift, as shown in Table 8. This means that the best forecast for the pass-through from exchange rates to IPA is the mean of the process. We can also note, according to Graph 7, that the only change in the behavior of the coefficient is the peaks in the early 1990s and a smaller volatility after the Real plan. However, the mean of the coefficient was relatively stable: 0.33 from 1980:I to 1994:II, 0.27 from 1994:3 to 98:4 and 0.31 from 1999:I on (see Appendix II). If we exclude the moments when there was a sharp decrease in the filtered coefficient (basically the same as with IPCA and IGP-DI: 1986:II, 1987:III, 1989:II, 1990:II, 1991:I, 1991:II, 1992:I, 1994:III, 1994:IV, 1999:II) – the mean goes to 0.37 between 1980:I and 1994:II and 0.32 between 1994:III and 1998:IV.

Graph 6 – IPA: Smoothed estimate of $m_{2,t}$ 

Graph 7 – IPA: Smoothed estimate of $a_{2,t}$ 

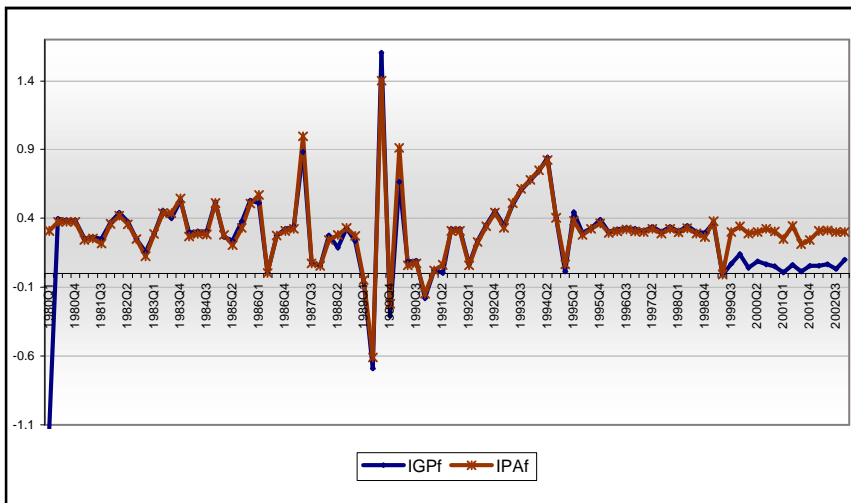

The values presented here are quite high compared to the ones found for the other two indices. As they are close to the unit, they also suggest a virtually complete pass-through from exchange rate to wholesale prices. This result seems to demonstrate what the economic theory had already predicted: wholesale prices are more strongly affected by exchange rate movements and, in the absence of nontradables, the pass-through from exchange rate to inflation is almost complete.

An explanation to this behavior can be found in the theoretical model developed in this paper. Since Brazil is a small economy, it is a price-taker in the foreign market and it is not able to affect international prices as predicted by the pricing-to-market models applied to developed economies¹⁴. A smaller pass-through to consumer prices (IPCA and IGP) reflects the absorption of the exchange rate by retailers, which can be explained – given the maximization model presented in this paper – by an attempt to avoid a reduction in demand that is not offset by a rise in prices. This does not necessarily mean losses for the agents, but only a change in their profit margins.

14 Those models consider that, in face of an exchange rate devaluation in country B, the exporting firm in country A will reduce its exporting prices for B in order not to have a high reduction in sales in that country, given the weight of that market on its global demand. The result of such an action is that prices in B will rise less than proportionally to the exchange rate devaluation, resulting in an incomplete pass-through and evidence of the rejection of PPP.

As we noticed, answer of IPA-DI to exchange rate variations is relatively stable, no matter the period we focus on. Comparing the smoothed estimates of the pass-through to IPA with those to IGP, we notice an interesting feature. Until 1998:IV, the exchange rate pass-through to these indices were, basically, the same. Before 1999, the exchange rate was fixed and changes in those rates were considered to be permanent, causing adjustments in prices by agents. With the floating rate, price setters do not know if the variation is permanent or transitory and, hence, choose, many times, to postpone price changes until exchange rates stabilize in a given level. The gap between IPA and IGP after 1999 (see graph 8) may be a result of the drop in the exchange-rate pass-through in the consumer-price component of the IGP. Another reason for that gap may be the methodology by which the IPA is calculated. Those are not the actual prices producers find in the market (as in consumer prices) but they are sort of menu prices, reflecting the prices producers intend to charge for their products. Therefore, one can guess that producers intend to pass-through the same proportion of a given devaluation to prices. However, market conditions are the ones who will tell if such pass-through will be concluded or not, a fact not revealed by the IPA but by consumer prices.

**Graph 8 – Smoothed estimates of $a_{1,t}$ to post-Real period:
IGP-DI vs. IPA-DI**

6. Comparison of Results

According to the results obtained herein, there is a decrease in the pass-through from the exchange rate to IPCA and IGP-DI after the stabilization of the Real, and a sharper one after the shift in the exchange rate regime in 1999. Before 1999, the effects of an exchange rate shock in period t on IGP-DI would be complete after approximately four quarters (considering the absence of further shocks). After 1999, only 32% of the shock would have been absorbed by the index in an equal period. For IPCA, between 1980 and 1998, the pass-through of the shock would be complete in two quarters before 1999, but after that year it would represent only 7%. The exception is IPA-DI, which keeps an almost complete pass-through in the third quarter.

The exchange rate pass-through behavior found in the present paper is in line with other estimates reported in the literature. MINELLA, FREITAS, GOLDFAJN and MUINHOS (2003) analyzed the post-Real period and also found a change in the exchange rate pass-through to prices after 1999 (considering the 12-month exchange rate variation with one lag). However, the magnitude of the change is different, depending on the approach adopted: the Central Bank's structural model, the Phillips curve, or a VAR model. Nonetheless, the graph of the recursive estimation of the coefficients found in the Phillips curve for IPCA is very similar to Graph 2 presented in section 5.3.1 of this paper.

The results for IPCA in the post-Real period are also similar to the ones presented by MUINHOS and ALVES (2003) for free prices – which correspond to approximately 70% of IPCA – by applying a non-linear Phillips curve. The authors found an exchange rate pass-through of 0.51 between 1995:I and 1998:IV and of 0.06 from 1999:I on. The values observed for the period after 1999 are also similar to the ones presented by CARNEIRO, MONTEIRO and WU (2002), who found a quarterly exchange rate pass-through between 1999 and 2002 of 6.4% on average.

GOLDFAJN and WERLANG (2000) found a six-month accumulated pass-through of about 21% for European economies and 38% for emerging ones between 1980 and 1998. HAUSSMAN, PANIZZA and STEIN (1999) also encountered different pass-through values among the analyzed countries. For instance, the USA, the UK and Japan have an average 12-month accumulated pass-through of 3%; Germany, Canada

and Norway, 7%; Switzerland, Greece, Israel and Korea, 16%; Australia and Peru, 21%, and Mexico, Paraguay and Poland, over 50%, among others.

Results are also in line with BELAISCH (2003) who estimated a 6% pass-through to IPCA and 34% to IPA in a three-month period through a VAR model with monthly data for the 1999:07 to 2002:12 period. However, the IGP result is quite distinct, with the author finding a quarterly pass-through of around 27%. As we mentioned in the IGP-DI analysis, that is the value we found for the 1994:III to 1998:4 period. The drop in 1999:I is due to the inclusion of the dummy d_2 . Without d_2 , the model would not identify the change, but the coefficient would be statistically equal to zero, leading us to reject that result. A reason for the difference may be a methodological issue. Belaisch calculates the pass-through coefficient as the reason between accumulated inflation after the exchange rate shock and accumulated pass-through, variations obtained by a cumulative impulse-response function. However, the author has a quite small sample to a VAR model.

MUINHOS (2001) uses a sample with quarterly data from 1980 to 2000, different estimations of the Phillips curve, with and without an expectation term and with linear and non-linear specifications (the latter of which contains cross-terms), also including a short sample relating to the period after 1995. The results of the linear specification point towards a pass-through coefficient of 0.10 in the small sample if the expectation term is not included, and of 0.09 if this term is included. In the non-linear specification, the pass-through coefficients are 0.24 without the expectation term, 0.12 with the term, and 0.55 for the whole sample. However, the results do not indicate changes in the exchange rate pass-through after 1995 in the whole sample, or in both samples, after 1999. When the authors show the behavior of pass-through coefficients after 1998 for the small sample, there is a break in this coefficient after the floating exchange rate regime was adopted. The average coefficient for 1998 is, in this case, higher than 0.5 while it is of about 0.1 after 1999, a result that is in line with the ones presented in this paper. Nevertheless, such change is not identified in the whole sample (1980 to 2000) when the coefficient for 1998 is also around 0.1.

7. Final Remarks

Some conclusions may be drawn in light of what was discussed in this paper. The first conclusion is that the model developed from a pricing-to-market approach is able to indicate changes that occurred in the exchange rate coefficient throughout the study period. Furthermore, amongst the tested formulations, non-linear models and time-variant coefficients are more suitable than OLS coefficients with time-invariant parameters, even when the sample is divided. The results obtained by MUIINHOS (2001) who, as other previously mentioned authors, observed a decrease in the exchange rate pass-through after 1999 only when using the small sample, lend further support to the Kalman Filter to the detriment of time-invariant models, when such a long and complex period is analyzed.

In comparison with the results found by GOLDFAJN and WERLANG (2000) and by HAUSSMAN, PANIZZA and STEIN (1999), the data presented herein show that the pass-through from the exchange rate to prices in Brazil is not only smaller after the adoption of the floating exchange rate system in 1999, but also quite similar to the ones observed in stronger economies. Our paper shows that the macroeconomic environment affects the way consumer prices will respond to exchange rate movements, as supposed by literature (see GOLDFAJN and WERLANG, 2000) being possible to identify three different patterns in the pass-through coefficient to the IPCA and IGP-DI: the first one is characterized by a high inflation period, the second one concerns the period of low inflation and pegged exchange rates, and the third one refers to the period of stable prices and floating exchange rates. The presence of the dummy variable d_2 also suggests that the type of exchange rate regime observed by the agents – more than the one officially announced – also affects the response of prices to exchange rate movements.
